ABSTRACT: DÁVID L., Anthropogenic geomorphological and after-use problems of quarrying: case studies from the UK and Hungary. (IT ISSN 1724-4757, 2007).

The study intends to give an introduction to the significance of quarrying from the point of view of anthropogenic geomorphology, indicating the level of surface forming taken place due to the mining of these raw materials. The significance of this topic is supported by the presence of the so-called «mining landscapes» emerged since the 19th century. Authors focus on the geomorphic impact of quarrying with special emphasis on factors influencing its spatial distribution, as well as on the characteristics and classification of surface features produced by quarrying, providing an overview of the most important excavated and accumulated forms and form components on the macro, meso and micro scales. Finally, international and Hungarian case studies illustrate some aspects of the opening and after-use of mining sites in order to observe how abandoned quarries can be turned into «environmental values», and used as possible sites for exhibitions or for regional and tourism development projects.

KEY WORDS: Andesite quarries, Classification of man-made landforms, Land reclamation, North-Hungary.

INTRODUCTION

There is no need to explain in details the close relationship between mining activities and geology as well as geomorphology. However, it should be mentioned that researchers only became interested in the problems of geomorphic impact at a rather late stage of evolution of these sciences. It is well illustrated by fig. 1 that both international and Hungarian research on landscape alterations caused by raw material production only dates back to the 1960's.

Mining activities were revolutionized by developments in mining techniques and the application of steam engines from the 19th century thus the exploitation of various mineral raw materials eventuated in the emergence of «mining landscapes». As a whole, the most generally extracted substances for the building industry embrace the raw materials for the cement and lime industry, building and ornamental stones, sands and gravels as well as clays for the porcelain industry. This study intends to give an introduction to the significance of quarrying from the point of view...
of anthropogenic geomorphology, indicating the degree of surface transformation which took place due to the mining of raw materials.

GEOMORPHIC IMPACT OF QUARRYING

It can be claimed that the spatial distribution of quarrying, in general, is fairly even in a sense that if geological conditions provided, there are hardly any mountain settlements without a quarry of any scale opened in their surroundings during their history. When quarrying also aims to reach markets to a greater distance, market regulators (economically exploitable supplies, transportation expenditure and possibility, etc.) become more important, thus in some cases, quarrying can show a rather high concentration in space. The level of socio-economic development being decisive for the quantity and quality indicators of the material flow between user and its environment has undergone continuous changes during history. This is reflected by the extent of the montanogenic landforms (i.e. those produced by mining) on the one hand as well as in the rate of the expansion of areas affected by mining activity.

In addition to the geological conditions, the site selection of quarries is also controlled by the topography of the area (Dávid, 2006). Longwall face quarrying prevails on mountainous or hilly terrains whereas in flat areas deep mining is applied. However, intermediate types also occur occasionally. Exceptionally, closed work is applied, too, as in the case of Fertoárkos (NW-Hungary). As far as longwall face quarrying is concerned, it is the topography that is transformed to a visible extent, face walls of several hundred metres length and of some ten metres height may result, depending on the applied technology (fig. 2).

In cases when the rock material to be exploited is found under a flat or sloping surface, a quarry sunk in the surface has to be established. Such quarries are sometimes created through the lowering of the quarry floor by longwall face quarrying. If cover strata are too thick, extraction takes place from underground shafts or cavities. Apart from this, the characteristics of the quarried (metamorphic, igneous, or sedimentary) rocks are of decisive relevance as well as the adherence of the various mine safety regulations. All of them may also have an influence on the evolving features.

CLASSIFYING THE GEOMORPHIC IMPACT OF QUARRYING

As a result of quarrying, the landscape may undergo visible changes (tab. 1).

Forms created as a result of mining can be classified into three main groups (Dávid & Patrick, 1998a,b; Karancsi, 2000; Dávid, 2000):

a) excavated (“negative”) forms,
b) accumulated (“positive”) forms,
c) and forms destroyed by quarrying activities can be classified into another group on the basis of geotechnics.

This virtually means the levelling of the surface, which is called planation in geography.

The geomorphological study of quarrying features was undertaken in three categories, distinguished by origin and size (fig. 3). It should be noted, however, that there are several different approaches to classification (Erdősi, 1966, 1969, 1987; Karancsi, 2000). One of them, for instance, is by quarry location relative to geological formations and surface macroforms (Erdősi, 1987). Another takes the characteristics of the given area into account (Karancsi, 2000).

**Fig. 2 -** Siting of a quarry of several production levels (Ozoray, 1955).

**Fig. 3 -** Schematic layout of a quarry (Dávid & Karancsi, 1999). Legend: A) mine floor, B) mine wall, C) pillar, D) rock buttress, E) rock bench, F) outweathered rock, G) talus slope, H) rainwater groove, I) depression with a small pond, J) debris cone.
Macroforms are the most obvious traces of quarrying. Excavated macroforms may virtually be regarded as sur-
cfaces with material deficit (caverns). Accumulated macro-
forms are called mine dumps. Excavated macroforms
composed of smaller elements (excavated mesoforms).
Quarry walls and floors and debris aprons are distin-
guished in almost every extraction site. The morphological
components of accumulated macroforms are plateaux and
slopes (accumulated mesoforms). The surfaces of meso-
form components can be divided into smaller and larger
excavated depressions (possibly out-weathered sections)
or accumulated elevations that are called microforms. In
addition to the influence of quarrying technology and
working rate, the properties of features in all three cate-
gories are also controlled by the geological characteristics
of the area (structure, bedding), the nature of the rocks
and the natural processes affecting them.

Excavated (negative) forms

The most common and simple type of excavated form
is an excavation pit or a deepened. Excavated macroforms
of quarrying origin usually appeared before accumulated
forms, therefore examples of them can be found in the
first period of quarrying history. Mainly in the form of
small quarries they are found next to almost every town
and village in mountainous areas.

The other type of excavated forms results from multi-
levelled horizon mining (complex excavated type). It is in-
creasingly typical in modern times. The technical condi-
tion for its occurrence was the increase in the capacity and
efficiency of excavating equipment, while as far as geologi-
cal conditions are concerned, it was favoured by the pres-
ence of thick strata.

Excavated mesoforms are composed of the following
elements:

Mine wall: the steepest component, whose angle of incli-
nation to the floor is determined by quarrying technology
(blasting, hand or power excavation) as well as by rock
quality. It is normally subvertical. The quarry floor is usu-
ally surrounded by walls on three sides.

Debris cones, debris aprons: components with smaller an-
gles of repose lying at the foot of quarry walls. Their mate-
rials partly derive from quarry working and partly from
natural processes (rockfalls). They are initially developed
by accumulation but their origin is linked to excavation
activities. As material is accumulating in debris cones, they
may coalesce to form a continuous debris apron.

Quarry floor: an approximately flat ground surface sur-
rrounded by walls and debris aprons, including a range of
features (accumulations of quarry material, quarry heaps,
pillars etc.).

Common excavated microforms of quarrying are rock
counterforts, rock benches, out-weathered quarry columns,
pinnacles and pillars. The latter are basically transitional
features between excavated and accumulated forms as be-
ing the positive remnants of quarrying. They may resist the
damaging effects of natural processes and talus slopes of
various sizes are found in front of them. Precipitation wa-
ter may collect in small shallow ponds in the depressions
of the quarry floor.

Accumulated (positive) forms

Accumulated macroforms are called quarry dumps. They are formed through the accumulation of waste, which is currently of no value from an economic point of view. During open-cast mining dumps of various origins are heaped. By the removal of burden from above the material to be excavated, a significant amount of so-called sheathing dump is created. This material (interstage and plant dump) can also be a result of the extraction and processing of the material, i.e. during grinding or crushing. The granulometric composition of quarry dumps is rather diverse, being influenced not only by geological conditions but also by the method of processing. There can also be different shapes of dumps, as curve-, fan- and round-shaped dumps created at the end of bankfills are distinguished. In addition, temporary storing of the quarry material also has to be referred to this group. They are found isolated (simple accumulated type) or in groups (complex accumulated type).

The shape of a positive form is determined by several factors: the original ground surface, the mode of accumulation and the physical features of the dump material. Cone-shaped, truncated cone-shaped and terraced dumps are the most common.

Common components of accumulated mesoforms are: Plateau: the relatively flat ground surface surrounded by the slopes of dumps. Its extent is determined by the type of the dump. The largest plateaux can be found on terraced dumps, while the plateaux of truncated cone-shaped dumps are usually smaller.

Slope: the sloping ground surface which surrounds the plateau or the peak in the case of a cone-shaped dump. Its inclination varies on a wide range depending on the mode of accumulation, the dump material and the initial ground surface.

The most obvious microforms of dumps, formed by natural processes, are gullies cut into slopes. They are arranged radially on cone-shaped or truncated cone-shaped dumps. The dump material carried by rainwater settles in small alluvial cones at footslopes. Flat-topped plateaux may be dissected by headward eroding gullies. The accumulated microforms of quarry floors, formed as a result of quarrying, are larger heaps and boulders dissecting the approximately flat ground surface.

Planation

Quarrying does not only construct landforms but it can also result in planation. With the spreading of dump material over natural or artificial dips (slopes, valleys, pits or depressions), they may be filled. Another possibility is the excavation of whole mountains during quarrying activities, resulting in huge landscape scars.
USE OF QUARRYING SITES AFTER CLOSURE

Until recently abandoned quarries both in Hungary and abroad has raised negative, unpleasant associations as “scars in the landscape” (fig. 5).

However, a new assessment is also encountered according which abandoned quarries are regarded as ‘environmental values’. They are appreciated as possible sites for several uses (exhibition sites or scenes for regional and tourism development projects). The case studies below intend to provide a brief overview.

Bluewater Shopping Centre

In recent years, many precedents, mainly from Great Britain show that commercial centres (hyper and supermarkets) are constructed in old quarries outside cities and next to them facilities for entertainment (parks, multiplex cinemas, gaming-rooms, concert halls, discos, galleries, art centres, etc.) are also developed (Bennett & Doyle, 1999). The most outstanding example for this is the Blue Water Shopping Centre located in Dartford at Junction No. 2. of the London Ring Road M25, marketed as the largest entertainment centre of this kind in Europe. This investment compelling both in its outside and inside appearance has been built between 1995 and 1999, in the area of the abandoned Blue Circle Chalk Quarry (fig. 6).

Patkó Quarry, Tokaj, NE-Hungary

The former quarry hosted a large-scale cultural event on 30 June, 2002, functioning as a “festival cauldron”. The event took place on the occasion that the Tokaj-Hegyalja Region was awarded the UNESCO World Heritage status in the category of cultural landscapes. Cultural programs were organised in the quarry to celebrate it. Since then it has been regularly used as a site for similar events.
